INTERNATIONAL APPLICATION PUBLISHED UNDER THE PATENT COOPERATION TREATY (PCT)

(54) Title: SYSTEM FOR ENCODING AND DECODING LAYERED COMPRESSED VIDEO DATA
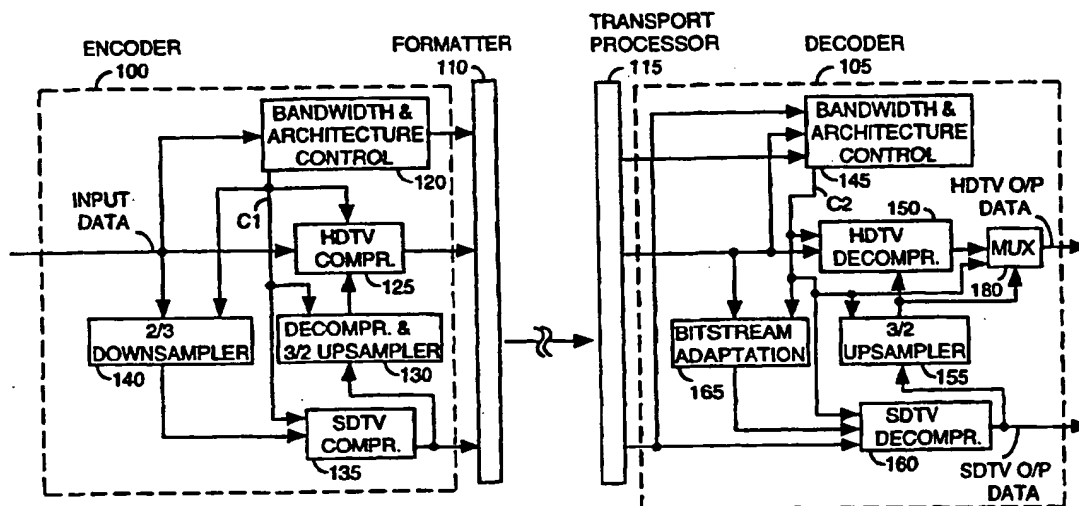

(57) Abstract

A dynamically configurable video signal processing system processes data in the form of hierarchical layers. The system partitions data between hierarchical layers and allows variation in the number of layers employed. Data is automatically partitioned into one or more hierarchical layers as a function of one or more parameters selected from available system bandwidth, input data rate, and output signal quality. In addition, the image resolution and corresponding number of pixels per image of the data may be varied as a function of system parameters. Both encoder (100) and decoder (105; 107; 109) systems are disclosed.

System for Encoding and Decoding Layered Compressed Video Data

5

This invention is related to the field of digital image signal processing, and more particularly to a system for processing hierarchical video data.

10   An objective in the development of digital video encoding and decoding formats has been to provide a standard that accommodates different video transmission and reception systems. A further objective has been to promote interoperability and backward compatibility between different generations and 15 types of video encoding and decoding equipment. In order to promote such interoperability and compatibility, it is desirable to define encoding and decoding strategies which can accommodate different types of video image scan (e.g. interlaced/progressive), frame rate, picture resolution, frame size, chrominance coding, and 20 transmission bandwidth.

One strategy used to achieve interoperability involves separating video data into one or more levels of a data hierarchy (layers) organized as an ordered set of bitstreams for 25 encoding and transmission. The bitstreams range from a base layer, i.e. a datastream representing the simplest (e.g. lowest resolution) video representation, through successive enhancement layers representing incremental video picture refinements. The video data is reconstructed from the ordered bitstreams by a 30 decoder in a receiver. This strategy permits decoder complexity to be tailored to achieve the desired video picture quality. A decoder may range from the most sophisticated configuration that decodes the full complement of bitstreams, that is all the enhancement layers, to the simplest that decodes only the base layer.

35

2

A widely adopted standard that uses such a data hierarchy is the MPEG (Moving Pictures Expert Group) image encoding standard (ISO/IEC 13818-2, 10th May 1994), hereinafter referred to as the "MPEG standard". The MPEG standard details
5 how the base and enhancement layer data may be derived, and how the video data may be reconstructed from the layers by a decoder. It is herein recognized that it is desireable to provide a system that incorporates encoder and decoder architectures for rationally partitioning data between the various layers and for
10 dynamically configuring such a system for this purpose.

In accordance with the principles of the present invention, dynamically configurable video signal processing systems enable data allocation among hierarchical layers to be
15 varied. The dynamically configurable systems also permit the data to be partitioned between the hierarchical layers as desired, and allow variation in the number of layers employed.

A disclosed digital signal processing system according
20 to the present invention adaptively processes a datastream of image representative input data. A data processor automatically partitions input data into one or more hierarchical layers as a function of one or more parameters selected from available system bandwidth, input data rate, and output signal quality.
25
Also disclosed is a digital signal processing system for adaptively decoding a datastream of image representative input data partitioned into one or more hierarchical layers. The decoding system derives synchronization and configuration information
30 from the input data and is adaptively configured to decode the number of hierarchical layers of the input data in response to a locally generated Control signal.

3

In accordance with a feature of the invention, the image resolution and corresponding number of pixels per image is varied as a function of system parameters.

5   Brief Description of the Drawings

In the drawing:

Figure 1 shows an exemplary dynamically configurable
10 video signal encoding and decoding architecture, according to the invention.

Figure 2 depicts an exemplary graph of Peak Signal to Noise Ratio (PSNR) plotted against Bit Rate that indicates different
15 coding strategy regions, according to the invention.

10   Figure 10 presents a flowchart of a method for identifying the region type of the input data, according to the invention.

The MPEG standard refers to the processing of 15 hierarchical ordered bitstream layers in terms of "scalability". One form of MPEG scalability, termed "spatial scalability" permits data in different layers to have different frame sizes, frame rates and chrominance coding. Another form of MPEG scalability, termed "temporal scalability" permits the data in different layers to have 20 different frame rates, but requires identical frame size and chrominance coding. In addition, "temporal scalability" permits an enhancement layer to contain data formed by motion dependent predictions, whereas "spatial scalability" does not. These types of scalability, and a further type termed "SNR scalability", (SNR is 25 Signal to Noise Ratio) are further defined in section 3 of the MPEG standard.

An embodiment of the invention employs MPEG "spatial" and "temporal" scalability in a 2 layer hierarchy (base 30 layer and single enhancement layer). The enhancement layer data accommodates different frame sizes but a single frame rate and a single chrominance coding format. Two exemplary frame sizes correspond to HDTV (High Definition Television) and SDTV (Standard Definition Television) signal formats as proposed by the 35 Grand Alliance HDTV specification in the United States, for

5

example. The HDTV frame size is 1080 lines with 1920 samples per line (giving 1080 x 1920 pixels per image), and the SDTV frame size is 720 lines with 1280 samples per line (giving 720 x 1280 pixels per image). Both the HDTV and SDTV signals employ a
5 30 Hz interlaced frame rate and the same chrominance coding format.

    Although the disclosed system is described in the context of such an MPEG compatible, two layer HDTV and SDTV
10 spatially and temporally scalable application, it is exemplary only. The disclosed system may be readily extended by one skilled in the art to more than two layers of video data hierarchy and other video data resolutions (not only 720 and 1080 line resolution). Additionally, the principles of the invention may be applied to
15 other forms of scalability, such as SNR scalability, and also may be used to determine a fixed optimum encoder and decoder architecture. The principles of the invention have particular application in TV coding (HDTV or SDTV), Very Low Bit Rate Coding (e.g. video conferencing) and digital terrestrial
20 broadcasting for optimizing encoder and decoder apparatus for a desired communication bandwidth.

    Figure 1 shows a dynamically configurable video signal encoding and decoding architecture according to the
25 invention. In overview, an input video datastream is compressed and allocated between a base (SDTV) data layer and an enhancement (HDTV) data layer by encoder 100. The allocation is performed in accordance with principles of the invention under the control of bandwidth and architecture control unit 120. The
30 resulting compressed data from encoder 100 in the form of single or dual bitstreams is formed into data packets including identification headers by formatter 110. The formatted data output from unit 110, after transmission over a data channel, is received by transport processor 115. The transmission and

6

reception process is described later in connection with the encoding and decoding system depicted in Figure 4.

Transport processor 115 (Figure 1) separates the
5 formatted compressed bitstream data according to layer type, i.e. base or enhancement layer data, based on an analysis of header information. The data output from transport processor 115 is decompressed by decoder 105. The architecture of decoder 105 is determined in accordance with principles of the invention under
10 the control of bandwidth and architecture control unit 145. A resulting decompressed data output from decoder 105, in the form of single or dual decompressed bitstreams, is suitable for encoding as an NTSC format signal and for subsequent display.

15   Considering the dynamically configurable architecture of Figure 1 in detail, an input video datastream is compressed and allocated between a base SDTV data layer and an enhancement HDTV layer by encoder 100. Bandwidth and architecture control unit 120 configures the encoder 100 architecture to appropriately
20 allocate data between the HDTV and SDTV output layers from units 125 and 135 respectively. The appropriate data allocation depends on a number of system factors including bandwidth, system output data rate constraints, the data rate and picture resolution (number of pixels per image) of the input video data,
25 and the picture quality and resolution (number of pixels per image) required at each layer. In the described system, the image resolution between input and output of both encoder 100 and decoder 105 is varied by changing the number of pixels per image as described in greater detail later.
30
          The data allocation and encoding strategy is derived by determining the minimum number of bits per unit time required to represent the video input sequence at the output of encoder 100 for a specified distortion. This is the Rate Distortion Function
35 for encoder 100. The Rate Distortion Function is evaluated,

7

assuming the input sequence is a Gaussian distribution source signal of mean μ and standard deviation σ. Further, applying a squared-error criterion to the Rate Distortion Function, R, of such a Gaussian input sequence, in accordance with the theory presented

5 in section 13.3.2 of *"Elements of Information Theory"* by T. M. Cover and J. A. Thomas, published by J. Wiley & Sons, 1991, gives,

$$R = \frac{1}{2} max \; (0, \frac{1}{2} \log_2(\frac{\sigma^2}{D})), \qquad \text{(bits per second)}$$

10
$$= \frac{1}{2} \log_2(\frac{\sigma^2}{D}) \quad \text{if } 0 \le D \le \sigma^2$$

or,
$$= 0 \qquad \qquad \text{if } D > \sigma^2.$$

Therefore, the Distortion Rate Function, D, is given by,

15
$$D = \sigma^2 2^{-2R}$$

which, when represented as a Peak Signal to Noise Ratio (PSNR), is

$$D_{PSNR} = 10 \log(\frac{255^2}{\sigma^2}) + 20 \log (2 * R)$$

20   Figure 2 is a graphical representation of Distortion Peak Signal to Noise Ratio D_{PSNR} in decibels (dB), plotted against the Bit Rate of an Enhancement layer (bits per second) for a two layer spatial encoded system. Curves are plotted for a base layer distortion function, an enhancement layer distortion function, and

25 a distortion function for an exemplary upsampled base layer for a 1080 line interpolation of a 720 line picture. The base layer and upsampled base layer curves have a negative slope because as the bit rate of the Enhancement layer increases, the base layer bit rate decreases. The composite distortion curve for the 2 layer system is

30 shown by the thick black line of Figure 2. This composite Distortion curve is a linearized approximation to the minimum

8

Distortion obtainable for the 2 layer system employing an upsampled base layer.

An encoding and decoding strategy is derived from the
5 two layer system results depicted in Figure 2. In particular, three regions A, B and C are identified in which advantage can be gained by adopting different encoding and decoding approaches. The boundaries of these regions may vary depending on the system bandwidth, system output data rate constraints, the data rate and
10 picture resolution of the input video data and the picture quality and resolution required at each layer. The regions are identified as follows.

Region A.
15   In region A there is insufficient allocable bandwidth to achieve the required picture quality using either two layer encoding or a single high resolution layer encoding. In this region the video quality of a decoded upsampled base layer equals or exceeds the quality of a decoded picture derived from combined
20 base layer and enhancement layer data. This region is bounded at its upper end at a point X on the enhancement layer curve that gives a picture quality (D_{PSNR} value) equivalent to that of the upsampled base layer curve at the zero Bit Rate Enhancement layer point Y.
25

In region A there is an advantage in allocating the full available system bandwidth to the encoding and compression of a single layer (the base layer) at a reduced spatial resolution with a reduced number of pixels per image. This strategy may be
30 implemented in various ways. One way, for example, is to downsample an input datastream to provide a single base layer (SDTV) for transmission, and then to decode the corresponding received base layer to provide an SDTV decoded output upon reception. A higher resolution HDTV decoded output may be

9

produced at a receiver in addition to the SDTV decoded output by upsampling (oversampling) the decoded SDTV output. The advantage of this strategy arises because scarce bandwidth is more efficiently used when it is allocated to encode a lower 5 resolution single layer bitstream than when it is used to encode either two layers or a single high resolution layer. This is because these latter approaches typically incur greater encoding overhead associated with required additional error protection and data management code, for example. The region A type of situation 10 may occur, for example, when the total available system bandwidth is insufficient to support full resolution encoding. The advantage of the region A encoding approach may also arise in other situations, for example, when an input datastream to be encoded contains significant non-translational motion. Then, 15 region A spatial down and up sampling may provide better picture quality in a bandwidth constrained system than can be provided by motion compensated prediction encoding. This is because of the overhead associated with such motion compensation. The region A operation is discussed in greater 20 detail in connection with Figure 5.

Region B.

In region B, there is sufficient system bandwidth to meet the required output picture quality using a two layer 25 encoding strategy. In this region, the available system bandwidth is allocated between layers so that the quality requirements of both the decoded high and low resolution outputs are met. This region lies between region A and region C.

30   In region B, the system bandwidth is allocated   in accordance with picture quality requirements between high resolution and low resolution signal output layers. The two output layers may be encoded for transmission in various ways. One way, for example, is to downsample and encode the high resolution 35 input datastream to provide a low resolution (SDTV) layer for

transmission, and to decode this low resolution layer when received to provide a low resolution SDTV signal. The high resolution (HDTV) enhancement layer to be transmitted may be derived from a combination of an upsampled version of the

5   encoded SDTV layer and previous frames of the encoded HDTV layer. The HDTV decoded output may be derived from a combination of an upsampled version of the decoded SDTV output and the received encoded HDTV layer. This operation is discussed in greater detail in connection with Figure 6.

10

Region C.

In region C, the required picture quality cannot be achieved by allocating the system bandwidth either to encode two layers or to encode a single (low resolution) layer. In this region, a

15 high quality output video signal may be achieved, given the system bandwidth constraint, by encoding a single high resolution layer. This region is bounded by a point V on the enhancement layer curve that provides the level of picture quality required as a minimum for the base layer alone (equal to D_{PSNR} value W of

20 Figure 2).

In region C there is an advantage in allocating the full system bandwidth to the encoding and compression of a single layer (the enhancement layer) at full spatial resolution with a full

25 number of pixels per image. This strategy may be implemented in various ways. One way, for example, is to encode the input datastream at full spatial resolution as a single high resolution enhancement (HDTV) layer for transmission, and to decode the corresponding received enhancement layer to provide the high

30 resolution HDTV output. At a receiver, a low resolution (SDTV) output may be derived from the received high resolution signal by downsampling in the compressed or decompressed domain as described later. The advantage of this region C strategy arises because, given the required output picture quality level, the

11

available bandwidth is more efficiently used when it is allocated to encode a single high resolution layer rather than when it is used to encode two layers for transmission. This is because two layer' encoding requires additional error protection and data
5 management overhead information. This region C operation is discussed in greater detail in connection with Figure 7.

The three regions (A, B and C) identified for the 2 layer
10 system of Figure 2 may not all be present in every 2 layer system. For example, only one or two regions may be identified depending on the system bandwidth, system data rate constraints, and the picture quality and resolution required at each layer. Conversely, in systems involving more than two layers, more than three
15 regions may be identified in accordance with the principles of the invention. However, irrespective of the number of data regions identifiable in a system, adequate decoded picture quality may be achieved using encoding and decoding architectures configurable for only a limited number of the identifiable regions.
20

The different encoding and decoding strategies associated with regions A, B and C are implemented in the dynamically configurable architecture of Figure 1. In encoder 100, the appropriate strategy and architecture for allocating data
25 between the HDTV and SDTV output layers is determined by control unit 120. Control unit 120, e.g. including a microprocessor, configures the architecture of encoder 100 using the process shown in the flowchart of Figure 3. Control unit 120 first identifies the region type of the input data in step 315 of Figure 3 following
30 the start at step 310. The region type is determined in accordance with the previously discussed principles based on factors including the available system bandwidth, the data rate of the input datastream and the picture quality required of each decompressed output layer. These factors may be pre-
35 programmed and indicated by data held in memory within control

12

unit 120 or the factors may be determined from inputs to control unit 120. For example, the data rate may be sensed directly from the input datastream. Also, externally sourced inputs may originate from operator selection, for instance, and be input to 5 control unit 120 via a computer interface, for example. In one implementation, for example, control unit 120 may derive input data rate threshold values establishing the boundaries between regions A, B and C based on the preprogrammed values indicating system bandwidth and required picture quality of each 10 decompressed output layer. Then, control unit 120 adopts the appropriate region A, B or C encoding strategy based on the data rate of the input datastream reaching particular thresholds. Alternatively, the input data rate threshold values may themselves be preprogrammed within unit 120.
15

The region type of the input data is identified in step 315 of Figure 3 using the method shown in the flowchart of Figure 10. In step 515 of Figure 10, following the start at step 510, a single hierarchical layer and 1080 line image resolution is initially 20 selected for encoding the data in the coding region. The predicted Distortion factor for the input data when it is encoded as a single layer for transmission with 1080 line resolution is computed in step 525. Step 530 directs that steps 515 and 525 are repeated to compute the Distortion factors for a single layer encoding 25 implementation with 720 line resolution. Also, step 530 directs that steps 515 and 525 are further repeated to compute the Distortion factors for a two layer encoding implementation with both 720 and 1080 line resolutions. The resultant Distortion factors are compared and the image resolution and number of 30 hierarchical layers used for encoding are determined in step 540. The selection process ends at step 550. The number of layers and image resolution are selected in step 540 to give the minimum Distortion factor. This layer and resolution selection process implements the coding region identification function of step 315 35 (Figure 3). It should be noted that this method of partitioning

encoded input data is also useable for a variety of applications in which data is to be prepared for transmission and is not restricted to image processing. For example, the process may be used for telephony, satellite or terrestrial communication including 5 microwave and fibre-optic communication. Further, this process can encompass other types of data and the partitioning of data into other types of data segments or data packets, not just hierarchical layers of encoded data. The process may also encompass different numbers of data segments and data 10 resolution not just the two layers and the two data resolutions described with respect to the preferred embodiment.

If region A is selected, step 320 (Figure 3) directs that step 325 is performed and encoder 100 is configured for a type A 15 architecture. In addition, formatter 110 encodes the transmitted bitstream to indicate the region type of the data and the appropriate decoding architecture using information provided by control unit 120. Decoder 105 is compatibly configured to decode the transmitted region A type data in response to the encoded 20 architecture information. If the data is region C type, step 330 directs that step 335 is performed. Step 335 provides that encoder 100 is configured for a region C architecture, and the transmitted bitstream is updated to indicate the data and decoding architecture type in the manner described for region A. If the data 25 is not region C type, step 330 directs that step 340 is performed. Step 340 provides that encoder 100 is configured for a region type B architecture and the transmitted bitstream is updated to indicate the data and decoding architecture type in the manner described for region A.
30

Control unit 120 configures encoder 100 via a Configuration signal C1 that is provided to each of the constituent elements of encoder 100. Control unit 120 updates the configuration of encoder 100 for individual input data packets 35 where each data packet consists of sequences of code words and

14

represents a group of pictures e.g. a Group of Pictures in accordance with the MPEG standard. However, control unit 120 may update the encoder 100 configuration for different data packet lengths as appropriate for a particular system. For 5 example, the configuration may be performed at power-on, for each picture, for each picture stream (e.g. program), for each pixel block (e.g. macroblock), or at variable time intervals.

In region A operating mode, control unit 120 disables, 10 via the Configuration signal, both HDTV compressor 125 and 2:3 upsampler 130. In the resulting configuration of encoder 100 a single SDTV output layer is provided to formatter 110 by unit 135 of unit 100 for transmission. This configuration is shown and discussed in connection with Figure 5. Continuing with Figure 1, to 15 produce the SDTV layer output, 3:2 downsampler 140 reduces the spatial resolution of the 1080 line resolution input datastream by a factor of 2/3 to provide a 720 line output. This may be achieved by a variety of known methods including, for example, simply discarding every third line or preferably by performing an 20 interpolation and averaging process to provide two interpolated lines for every three original lines. The 720 line output from downsampler 140 is compressed by SDTV compressor 135 to provide SDTV layer compressed data to formatter 110. The compression performed by unit 135 employs a temporal 25 prediction process that uses prior SDTV layer frames stored within encoder 135. Such a compression process, involving temporal prediction and Discrete Cosine Transform (DCT) compression, is known and described, for example, in chapter 3 of the Grand Alliance HDTV System Specification of April 14, 1994, published 30 by the National Association of Broadcasters (NAB) Office of Science and Technology in their 1994 Proceedings of the 48th annual conference.

The resultant SDTV bitstream is formed into data 35 packets including identification headers and architecture

15

information by formatter 110. The architecture information is provided by control unit 120 and is encoded by formatter 110 into the transmitted bitstream using the "Hierarchy Descriptor" described in sections 2.6.6 and 2.6.7, of the MPEG image encoding

5 systems standard (ISO/IEC 13818-1, 10th June 1994). The architecture information is subsequently used by decoder 105 to compatibly configure decoder 105 for the appropriate decoding mode (e.g. region A, B or C mode). The configuration of decoder 105, like encoder 100, is updated for each transmitted data

10 packet. A data packet contains a group of pictures in this preferred embodiment.

Although using the MPEG "Hierarchy Descriptor" is the preferred method of ensuring encoder 100 and decoder 105 are

15 compatibly configured, other methods are possible. The architecture information may, for example, be encoded in MPEG syntax in the "User Data" field defined in section 6.2.2.2.2, of the MPEG standard. Alternatively, decoder 105 may deduce the appropriate decoding mode from the bit rate of the encoded

20 received data stream determined from the bit rate field of the sequence header per section 6.2.2.1 of the MPEG standard. The decoder may use this bit rate information together with pre-programmed data detailing the bandwidth and video quality requirements of the decoded output to deduce the appropriate

25 decoding mode in accordance with the previously described principles of the invention. The decoding mode may be changed, for example, when the received bit rate reaches pre-programmed thresholds.

30   The formatted compressed datastream output from unit 110 is conveyed over a transmission channel before being input to transport processor 115. Figure 4 shows an overall system including the elements of Figure 1 as well as transmission and reception elements 410-435. These transmission and reception

35 elements are known and described, for example, in the reference

16

text, *Digital Communication*, Lee and Messerschmidt (Kluwer Academic Press, Boston, MA, USA, 1988). Transmission encoder 410 encodes the formatted output from unit 110 (Figures 1 and 4) for transmission. Encoder 410 typically sequentially scrambles,
5 error encodes and interleaves the formatted data to condition the data for transmission prior to modulation by modulator 415. Modulator 415 then modulates a carrier frequency with the output of encoder 410 in a particular modulation format e.g. Quadrature Amplitude Modulation (QAM). The resultant
10 modulated carrier output from modulator 415 is then frequency shifted and transmitted by up-converter and transmitter 420 which may be, for example, a local area broadcast transmitter. It should be noted that, although described as a single channel transmission system, the bitstream information may equally well
15 be transmitted in a multiple channel transmission system, e.g. where a channel is allocated to each bitstream layer.

The transmitted signal is received and processed by antenna and input processor 425 at a receiver. Unit 425 typically
20 includes a radio frequency (RF) tuner and intermediate frequency (IF) mixer and amplification stages for down-converting the received input signal to a lower frequency band suitable for further processing. The output from unit 425 is demodulated by unit 430, which tracks the carrier frequency and recovers the
25 transmitted data as well as associated timing data (e.g. a clock frequency). Transmission decoder 435 performs the inverse of the operations performed by encoder 410. Decoder 435 sequentially deinterleaves, decodes and descrambles the demodulated data output from unit 430 using the timing data derived by unit 430.
30 Additional information concerning these functions is found, for example, in the aforementioned Lee and Messerschmidt text.

Transport processor 115 (Figures 1 and 4) extracts synchronization and error indication information from the
35 compressed data output from unit 435. This information is used in

17

the subsequent decompression performed by decoder 105 of the compressed video data output from processor 115. Processor 115 also extracts decoding architecture information from the MPEG Hierarchy Descriptor field within the compressed data from unit 5 435. This architecture information is provided to decoder bandwidth and architecture control unit 145 (Figure 1). Unit 145 uses this information to compatibly configure decoder 105 for the appropriate decoding mode (e.g. region A, B or C mode). Control unit 145 configures decoder 105 via a second Configuration signal 10 C2 that is provided to each constituent element of decoder 105.

In region A mode, control unit 145 of Figure 1 disables, via the second Configuration signal, both HDTV decompressor 150 and adaptation unit 165. In the resulting 15 configuration of decoder 105, the SDTV layer compressed video output from processor 115 is decompressed by SDTV decompressor 160 to provide a decompressed 720 line resolution SDTV output sequence. The decompression process is known and defined in the previously mentioned MPEG standard. In addition, 20 upsampler 155 oversamples the 720 line resolution SDTV output by a factor of 3/2 to provide a 1080 line resolution HDTV decompressed output. This may be achieved by a variety of known methods including, for example, interpolation and averaging to provide three interpolated lines for every two 25 original lines. The 1080 line resolution decompressed output from upsampler 160 is selected, via multiplexer 180 in response to the second Configuration signal, as the HDTV decompressed output sequence. The resulting decompressed HDTV and SDTV data outputs from decoder 105 are suitable for encoding as an NTSC 30 format signal by unit 440 of Figure 4, for example, and for subsequent display.

Figure 5 shows the encoder and decoder apparatus of Figure 1 configured for region A type encoding and decoding. The 35 functions of the elements shown are as previously described.

Upsampler 130 and HDTV compressor 125, shown in encoder 100 of Figure 1, are absent in Figure 5 since these elements are disabled in region A mode as previously described. Similarly, HDTV decompressor 150 and adaptation unit 165, shown in

5 decoder 105 of Figure 1, are absent in Figure 5 since these elements are disabled in region A mode also as previously described.

If the input data in Figure 1 is region B type, control

10 unit 120 configures encoder 100 for a region B architecture. This is done using the Configuration signal in a manner similar to that previously described for region A. However, in region B, encoder 100 compresses both high resolution and low resolution output layers for transmission, in contrast to the single low resolution

15 output compressed for region A. This configuration is shown and discussed in connection with Figure 6. Continuing with Figure 1, control unit 120 allocates the system bandwidth between the high resolution and low resolution output layers by configuring encoder 100 to compress enhancement data as a high resolution HDTV

20 output layer in addition to a low resolution SDTV output. This HDTV layer provides picture refinement data to enable decoder 105 to produce a 1080 line resolution picture output from the 720 line resolution SDTV layer.

25 The SDTV layer output in region B is produced in the same way as described for region A. The 720 line output from downsampler 140 is compressed by SDTV compressor 135 to provide SDTV layer compressed data to formatter 110. However, in region B, the high resolution HDTV enhancement layer for

30 transmission is derived by HDTV compressor 125. Compressor 125 derives the HDTV output by combining and compressing an upsampled decompressed version of the SDTV layer produced by upsampler/decompressor 130 and previous frames of the HDTV layer stored within compressor 125. Such a combination and

35 compression process involving temporal prediction performed by

19

compressor 125 is known and contemplated, for example, in the
spatial scalability section (section 7.7) of the MPEG standard. The
resulting HDTV and SDTV compressed outputs from encoder 100
are provided to formatter 110.

5

The HDTV and SDTV bitstreams from encoder 100 are
formed by formatter 110 into data packets including identification
headers and architecture information in the "Hierarchy Descriptor"
field. As described for region A, the formatted data from unit 110
10 is conveyed to transport processor 115 which provides the
architecture information to decompressor control unit 145 for
configuring decoder 105 (here for region B).

At the receiver, in region B mode, control unit 145
15 disables adaptation unit 165 using the second Configuration signal.
In the resulting configuration of decoder 105, the compressed
SDTV output from processor 115 is decompressed by unit 160 to
give a 720 line resolution SDTV output, as in region A. HDTV
decompressor 150 derives a decompressed 1080 line resolution
20 HDTV output by combining and decompressing an upsampled
version of this decoded SDTV output produced by upsampler 155
and previous frames of the HDTV layer stored within
decompressor 150. The process of combining the upsampled and
stored data and forming a decompressed output as performed by
25 decompressor 150 is known and described, for example, in the
spatial scalability section (section 7.7) of the MPEG standard. The
1080 line high resolution decompressed output from
decompressor 150 is selected as the HDTV decompressed output,
via multiplexer 180, in response to the second Configuration
30 signal. The resulting decompressed HDTV and SDTV data outputs
from decoder 105 are suitable for further processing and
subsequent display as previously described.

Figure 6 shows the encoder and decoder apparatus of
35 Figure 1 configured for region B type encoding and decoding. The

2 0

functions of the elements shown are as previously described. Adaptation unit 165, shown in decoder 105 of Figure 1, is absent in Figure 6 since this element is disabled in region B mode also as previously described.

5

If the input data in Figure 1 is region C type, control unit 120 configures encoder 100 for a region C architecture. This is done using the Configuration signal in a manner similar to that previously described for region A. However, in region C, encoder 10 100 encodes a single high resolution output rather than a low resolution output as for region A or two outputs as for region B. Control unit 120 allocates the full system bandwidth, if necessary, to encode a high resolution output and configures unit 100, via the Configuration signal, to encode the enhancement layer at a full 15 spatial (1080 line) HDTV resolution.

In region C mode, control unit 120 disables downsampler 140, SDTV compressor 135 and upsampler 130, via the Configuration signal. In the resulting configuration of encoder 20 100 the input sequence is compressed by HDTV compressor 125 using the full system bandwidth as required to provide a 1080 line resolution HDTV output to formatter 110. This configuration is shown and discussed in connection with Figure 7. Continuing with Figure 1, compressor 125 derives the HDTV output using previous 25 frames of the HDTV layer stored within compressor 125. The compression process performed by compressor 125 in region C is like that described for regions A and B and is also known.

The HDTV bitstream from unit 100 is formed by 30 formatter 110 into data packets including identification headers and architecture information in the "Hierarchy Descriptor" field. As described for region A, the formatted data from unit 110 is conveyed to transport processor 115, which provides the architecture information to decoder control unit 145 for 35 configuring decoder 105 (here for region C).

21

At the receiver, in region C mode, control unit 145
disables upsampler 155 using the second Configuration signal. In
the resulting configuration of decoder 105, the compressed HDTV
5 output from processor 115 is decompressed by unit 150 to give a
_1080 line high resolution HDTV output. This 1080 line
decompressed output from decompressor 150 is selected as the
HDTV decoded output of decoder 105, via multiplexer 180, in
response to the second Configuration signal. In addition, the
10 compressed HDTV output from processor 115 is adapted to meet
the input requirements of SDTV decompressor 160 by adaptation
unit 165. This is done by reducing the spatial resolution of the
compressed HDTV output from processor 115 to an effective 720
line resolution in the compressed (frequency) domain. This may
15 be performed, for example, by discarding the higher frequency
coefficients of those Discrete Cosine Transform (DCT) coefficients
that represent the video information of the compressed HDTV
output from processor 115. This process is known and described,
for example, in "*Manipulation and Compositing of MC-DCT
20 Compressed Video*" by S. Chang et al, published in the I.E.E.E.
Journal of Selected Area in Communications (JSAC), January 1995.
The spatially reduced compressed output from adaptation unit
165 is decompressed by unit 160 to give a 720 line resolution
SDTV output. The decompression processes performed by units
25 160 and 150 are like those described for region A and similarly
known. The resulting decoded HDTV and SDTV data outputs from
decoder 105 are suitable for further processing and subsequent
display as previously described.

30   Figure 7 shows the encoder and decoder apparatus of
Figure 1 configured for region C type encoding and decoding. The
functions of the elements shown are as previously described.
Downsampler 140, SDTV compressor 135 and upsampler 130,
shown in encoder 100 of Figure 1, are absent in Figure 7 since
35 these elements are disabled in region C mode as previously

22

described. Similarly, upsampler 155, shown in decoder 105 of Figure 1, is absent in Figure 7 since this element is disabled in region C mode.

5   Figure 8 is a variation of Figure 1 and shows an additional architecture configuration for region A decoding. The functions performed by encoder 100, formatter 110 and transport processor 115 of Figure 8 are as described for Figure 1. In addition, the functions of decoder 109 of Figure 8 are the same as 1 0 those of decoder 105 of Figure 1 except that in region A decoding, the 1080 line resolution HDTV decompressed output is provided in a different manner.

          In region A mode, decoder control unit 149 of Figure 8 1 5 disables, via the second Configuration signal, both upsampler 155 and adaptation unit 165. In the resulting configuration of decoder 109 the SDTV layer compressed video output from processor 115 is decompressed by SDTV decompressor 160 to provide the SDTV output of decoder 109. This is performed in the same manner as 2 0 described for Figure 1. However, the HDTV decompressed output from decoder 109 is produced by upsampling the SDTV layer in the frequency domain in contrast to the time domain sampling performed in decoder 105 of Figure 1. The compressed output from processor 115 in Figure 8 is upsampled in the compressed 2 5 (frequency) domain by adaptation unit 168 (not present in Figure 1). This may be performed, for example, by "zero padding" the higher order Discrete Cosine Transform (DCT) frequency coefficients that represent the video information in the compressed SDTV output from processor 115. In effect, selected 3 0 higher order DCT coefficients are assigned zero values. The theory behind this process is known and described, for example, in the previously mentioned *"Manipulation and Compositing of MC-DCT Compressed Video"* by S. Chang et al, published in the I.E.E.E. Journal of Selected Area in Communications (JSAC), January 1995. 3 5 The resultant upsampled output from adaptation unit 168 is

23

decompressed by HDTV decompressor 152 to provide the HDTV output from decoder 109. The resulting decompressed HDTV and SDTV data outputs from decoder 109 are suitable for processing and subsequent display as described in connection with Figure 1.

5

Figure 9 is a variation of Figure 1 and shows an additional architecture configuration for region C decoding. The functions performed by encoder 100, formatter 110 and transport processor 115 of Figure 9 are as described for Figure 1. In 10 addition, the functions of decoder 107 of Figure 9 are the same as those of decoder 105 of Figure 1 except that in region C decoding, the 720 line resolution SDTV decompressed output is provided in a different manner.

15   In region C mode, control unit 147 of Figure 9 disables, via the second Configuration signal, both upsampler 155 and SDTV decompressor 162. In the resulting configuration of decoder 107 the HDTV layer compressed video output from processor 115 is decompressed by HDTV decompressor 150 to provide the HDTV 20 output of decoder 107. This is performed in the same manner as described for Figure 1. However, the SDTV decompressed output from decoder 107 is produced by downsampling the HDTV layer in the time domain in contrast to the frequency domain sampling performed in decoder 105 of Figure 1. The decompressed HDTV 25 output from multiplexer 180 in Figure 9 is downsampled by downsampler 170 (not present in Figure 1) by a factor of 2/3 to provide a 720 line output. This may be performed by a variety of known methods as discussed with respect to downsampler 140 of encoder 100 in Figure 1. The 720 line resolution decompressed 30 output from downsampler 170 is selected as the SDTV decoded output of decoder 107, via multiplexer 175 (not present in Figure 1), in response to the second Configuration signal. The resulting decompressed HDTV and SDTV data outputs from decoder 107 are suitable for processing and subsequent display as described in 35 connection with Figure 1.

24

The encoder and decoder architectures discussed with
respect to Figures 1-9 are not exclusive. Other architectures may
be derived for the individual regions (A, B and C) that could
5   accomplish the same goals. Further, the functions of the elements
of the various architectures may be implemented in whole or in
part within the programmed instructions of a microprocessor.

25

CLAIMS:

1. A digital signal processing system for adaptively
processing a datastream containing input image representative
5 pixel data and for providing output data representing said input
image data, said system comprising:
            a data processor (100) with an input for receiving said
datastream, and for automatically partitioning said input image
representative data into a variable number of hierarchical layers
10 as a function of input data rate to provide partitioned data; and
            an output processor (110) responsive to said
partitioned data from said data processor for formatting said
partitioned data to be compatible with the requirements of an
output transmission channel to provide said output data.
15
            2. A system according to claim 1, wherein
            said data processor varies the number of pixels per
image of said partitioned data.

20   3. A system according to claim 2, wherein
            the number of pixels representing an image in said
output data, as conveyed to said transmission channel, is less than
the number of pixels representing a corresponding image in said
datastream.
25
            4. A system according to claim 1, wherein
            said data processor partitions said input image
representative data into a plurality of hierarchical layers of data
respectively corresponding to different numbers of pixels per
30 image.

26

5. A system according to claim 1, wherein

said data processor comprises a plurality of data processing networks including compression networks and sampling networks; and

5   the signal processing configuration of said data processing networks is automatically adapted as a function of parameters including at least one of available system bandwidth, input data rate, and signal quality.

10   6. A system according to claim 1, further including

a control network (120) for providing a configuration Control signal as a function of the data rate of said input image data; and wherein

said data processor comprises a compression network
15 (125-140) responsive to said Control signal for providing compressed image representative data as said partitioned data, wherein both the number of pixels per image of said compressed image representative data and said number of hierarchical layers are determined by the configuration of said compression network
20 in response to said configuration Control signal.

7. Apparatus according to claim 6, wherein

said compression network provides, in one configuration, output compressed data as a single layer with a
25 number of pixels per image substantially equal to the number of pixels per image of said image representative input data, and in another configuration, output compressed image data as a single layer with a number of pixels per image less than the number of pixels per image of said image representative input data.

30

27

8. Apparatus according to claim 6, wherein

output data produced by said output processor is in MPEG compatible format and contains information indicating the configuration of said compression network, wherein said
5 indicating information is encoded in an MPEG format field selected from at least one of the Hierarchy Descriptor field and the User Data field.

9. Apparatus according to claim 6, wherein
10   said number of hierarchical layers is varied in response to said configuration Control signal on a periodic basis defined by at least one interval selected from (a) an interval corresponding to the duration of a group of pictures, (b) an interval corresponding to the duration of a program stream, and
15 (c) an interval corresponding to the duration of a picture block.

10. Apparatus according to claim 6, wherein

said number of hierarchical layers is varied on a temporal basis.
20

11. Apparatus according to claim 6, wherein

said control network provides said configuration Control signal as a function of available bandwidth.

25   12. Apparatus according to claim 6, wherein

said control network provides said configuration Control signal as a function of the image quality required of output data from said output processor.

)

28

13. A digital signal processing system for adaptively decoding a datastream including image representative input pixel data partitioned into one or more hierarchical layers, said system comprising:

5   a processor (115) for deriving synchronization information from said datastream;

           a controller (145) for deriving configuration information from said datastream and providing a Control signal representing said configuration information; and

10   a decoder (150-180) for decoding said input pixel data using said synchronization information, said decoder being adaptively configured to decode the number of said hierarchical layers of said input pixel data in response to said Control signal.

15   14. A system according to claim 13, wherein said decoder exhibits one configuration for decoding a single hierarchical layer of image representative data containing a first number of pixels per image, and exhibits another configuration for decoding a single hierarchical layer of image
20 representative data at a reduced second number of pixels per image.

           15. A system according to claim 13, wherein said decoder decodes a plurality of hierarchical layers
25 corresponding to different numbers of pixels per image.

           16. A system according to claim 13, wherein the number of pixels of an image represented by output data from said decoder is different from the number of
30 pixels of an image represented by said input pixel data.

29

17.   A system according to claim 13, wherein
said input pixel data is compressed data; and
said decoder decompresses said number of said
hierarchical layers of said input pixel data and the number of
5 pixels per image of said input pixel data in response to said
Control signal.

18. Apparatus according to claim 17, wherein
said input pixel data is MPEG compatible data; and
10   said control network derives configuration information
from a field of said MPEG compatible data, said field being
selected from one of a User Data field, a Hierarchy Descriptor field
and a Bit Rate field.

15   19. Apparatus according to claim 17, wherein
said configuration information represents the data rate
of said input pixel data.

20. Apparatus according to claim 17, wherein
20   said decoder (a) in one configuration provides one
layer of decompressed image data with a number of pixels per
image substantially equal to the number of pixels per image of
said input pixel data, and (b) in another configuration provides
one layer of decompressed image data with a number of pixels per
25 image less than the number of pixels per image of said input pixel
data.

30

21. Apparatus according to claim 17, wherein

said input pixel data is subject to exhibiting variable image resolution as a function of the number of pixels per image; and

5   said decoder decompresses said input pixel data to provide decompressed image data with a predetermined number of pixels per image, wherein said input pixel data is subject to exhibiting at least two different numbers of pixels per image corresponding to different image resolutions.
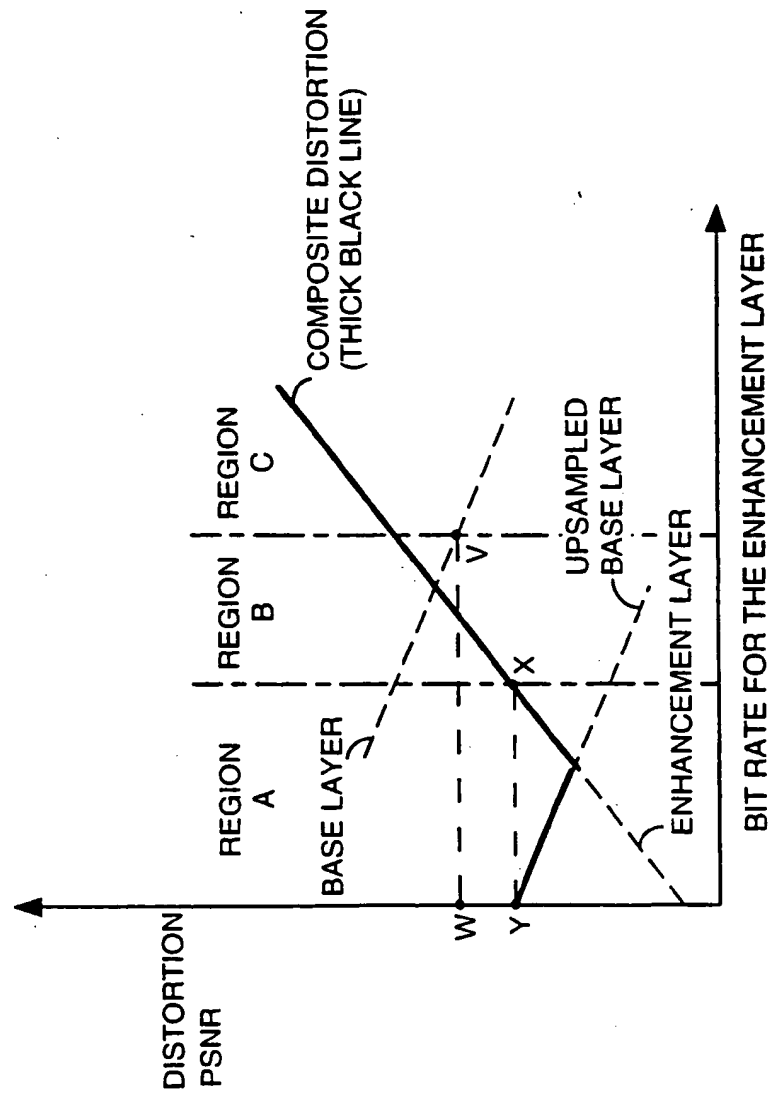

10

22. Apparatus according to claim 21, wherein

said decoder is adaptively configured on a temporal basis.
